Abstract

Using renormalization-group methods, differential equations can be obtained for the all-orders summation of leading and subsequent non-leading logarithmic corrections to QCD perturbative series for a number of processes and correlation functions. For a QCD perturbative series known to four orders, such as the e^+e^- annihilation cross-section, explicit solutions to these equations are obtained for the summation to all orders in α_s of the leading set and the subsequent two non-leading sets of logarithms. Such summations are shown for a number of processes to lead to a substantial reduction in sensitivity to the renormalization scale parameter. Surprisingly, such summations are also shown to lower the infrared singularity within the perturbative expression for the e^+e^- annihilation cross-section to coincide with the Landau pole of the naive one-loop running QCD couplant.

1 Optimal RG Improvement of $\Gamma(B \rightarrow X_u \ell^- \bar{\nu}_\ell)$

Optimal renormalization-group (RG) improvement of a perturbative series to a given order in the expansion couplant is the idea of including within that series all higher-order contributions that can be extracted by renormalization-group methods [1]. We call such terms, which involve leading and successive logarithms of the renormalization scale μ , RG-accessible. Techniques have been developed to obtain closed-form summations of such RG-accessible contributions to all orders in the perturbative expansion parameter, and such summations have been shown to lead to “optimally RG-improved” expressions for perturbative quantities that have significantly diminished dependence on μ [2, 3].

For example, leading and subleading perturbative QCD corrections to the inclusive semi-leptonic $B \rightarrow X_u \ell^- \bar{\nu}_\ell$ decay rate, which in tree-order is purely a charged-current weak interaction process, are given by a QCD series [4]

$$\begin{aligned} S = & 1 + \left[4.25360 + 5 \log \left(\frac{\mu^2}{m_b^2(\mu)} \right) \right] \left(\frac{\alpha_s(\mu)}{\pi} \right) \\ & + \left[26.7848 + 36.9902 \log \left(\frac{\mu^2}{m_b^2(\mu)} \right) + \frac{415}{24} \log^2 \left(\frac{\mu^2}{m_b^2(\mu)} \right) \right] \left(\frac{\alpha_s(\mu)}{\pi} \right)^2 \\ & + \mathcal{O} \left(\left(\frac{\alpha_s(\mu)}{\pi} \right)^3 \right) \end{aligned} \quad (1)$$

such that

$$\Gamma(b \rightarrow u \ell^- \bar{\nu}_\ell) = \frac{G_F^2 |V_{ub}|^2}{192\pi^3} m_b^5(\mu) S. \quad (2)$$

If one substitutes eq. (1) into eq. (2), one obtains a decay rate that decreases monotonically with increasing μ , raising the question as to which value of μ is most appropriate for comparing the calculation (2) to experiment. Clearly, such dependence on the unphysical parameter μ is an embarrassment; indeed the renormalization group equation for the series S

$$0 = \left[\mu^2 \frac{\partial}{\partial \mu^2} + \beta(g) \frac{\partial}{\partial g^2} + m_b \gamma_m(g) \frac{\partial}{\partial m_b} + 5 \gamma_m(g) \right] S[\mu^2, g^2(\mu), m_b(\mu)] \quad (3)$$

is nothing more than a chain rule expression for the requirement that the physically measurable decay rate be impervious to changes in the renormalization scale parameter μ ,

$$0 = \frac{d}{d\mu^2} \Gamma(B \rightarrow X_u \ell^- \bar{\nu}_\ell). \quad (4)$$

The residual μ -dependence of the decay rate obtained from the series (1) is necessarily a consequence of the truncation of that series, as well as the relatively large value of the expansion constant $\alpha_s(\mu)/\pi$.

In fact, the series (1) may be expressed as a double summation over powers of logarithms and the expansion parameter, i.e., in the following form:

$$S[x, L] = \sum_{n=0}^{\infty} \sum_{m=0}^n T_{n,m} x^n L^m, \quad (5)$$

where

$$x \equiv \alpha_s(\mu)/\pi, \quad L \equiv \log(\mu^2/m_b^2(\mu)). \quad (6)$$

The first few constants of this series, i.e., the set $\{T_{0,0}(=1), T_{1,0}, T_{1,1}, T_{2,0}, T_{2,1}, T_{2,2}\}$, are given by eq. (1). However, all higher-order constants of the form $T_{n,n}$, $T_{n,n-1}$ and $T_{n,n-2}$ can be obtained via eq. (3), and, hence, are RG-accessible. In terms of the new variables x and L , the RG-equation (3) may be expressed as

$$0 = \left[(1 - 2\gamma_m(x)) \frac{\partial}{\partial L} + \beta(x) \frac{\partial}{\partial x} + 5\gamma_m(x) \right] S[x, L]. \quad (7)$$

If we substitute the series (5) into the RG-equation (7), as well as the known QCD series expansions of the RG-functions

$$\beta(x) = - \sum_{n=0}^{\infty} \beta_n x^{n+2}, \quad \gamma_m(x) = - \sum_{n=0}^{\infty} \gamma_n x^{n+1}, \quad (8)$$

we find for any integer p that the aggregate coefficients of $x^p L^{p-1}$, $x^p L^{p-2}$ and $x^p L^{p-3}$ on the right hand side of eq. (7) necessarily vanish:

$$x^p L^{p-1} : \quad 0 = pT_{p,p} - \beta_0 T_{p-1,p-1}(p-1) - 5\gamma_0 T_{p-1,p-1} \quad (9)$$

$$\begin{aligned} x^p L^{p-2} : \quad 0 &= (p-1)T_{p,p-1} + 2\gamma_0(p-1)T_{p-1,p-1} - \beta_0(p-1)T_{p-1,p-2} \\ &- \beta_1(p-2)T_{p-2,p-2} - 5\gamma_0 T_{p-1,p-2} - 5\gamma_1 T_{p-2,p-2} \end{aligned} \quad (10)$$

$$\begin{aligned} x^p L^{p-3} : \quad 0 &= (p-2)T_{p,p-2} + 2\gamma_0(p-2)T_{p-1,p-2} + 2\gamma_1(p-2)T_{p-2,p-2} \\ &- \beta_0(p-1)T_{p-1,p-3} - \beta_1(p-2)T_{p-2,p-3} - \beta_2(p-3)T_{p-3,p-3} \\ &- 5\gamma_0 T_{p-1,p-3} - 5\gamma_1 T_{p-2,p-3} - 5\gamma_2 T_{p-3,p-3}. \end{aligned} \quad (11)$$

Given knowledge of $T_{0,0}(=1)$, one can calculate any coefficient $T_{p,p}$ through successive applications of eq. (9). Indeed the eq. (1) values $T_{1,1} = 5$ and $T_{2,2} = 415/24$ follow from just two successive iterations of (9) using the $n_f = 5$ QCD values $\gamma_0 = 1$, $\beta_0 = 23/12$. Similarly, knowledge of all $T_{p,p}$ coefficients, as obtained via (9), plus knowledge of $T_{1,0} = 4.25360$ [eq. (1)] is sufficient via successive applications of (10) to determine all coefficients $T_{p,p-1}$. Finally, knowledge of all coefficients $T_{p,p}$, $T_{p,p-1}$ plus the single coefficient $T_{2,0} = 26.7848$ is sufficient via successive applications of (11) to determine all coefficients $T_{p,p-2}$, since the set of $\overline{MS}$ RG-function coefficients $\beta_0, \beta_1, \beta_2, \gamma_0(=1), \gamma_1$, and γ_2 have all been calculated [5].

Since we now see that all coefficients $T_{p,p}$, $T_{p,p-1}$ and $T_{p,p-2}$ are RG-accessible, it makes sense to restructure the double-summation series (4) in the form

$$S[x, L] = \sum_{p=0}^{\infty} T_{p,p} x^p L^p + \sum_{p=1}^{\infty} T_{p,p-1} x^p L^{p-1} + \sum_{p=2}^{\infty} T_{p,p-2} x^p L^{p-2} + \sum_{p=3}^{\infty} T_{p,p-3} x^p L^{p-3} + \dots, \quad (12)$$

since the first three terms above are completely determined by eqs. (9), (10) and (11). We express (12) in the more compact form

$$\begin{aligned} S[x, L] &= \sum_{n=0}^{\infty} x^n \left[\sum_{p=n}^{\infty} T_{p,p-n} (xL)^{p-n} \right] \\ &\equiv \sum_{n=0}^{\infty} x^n S_n(xL) \end{aligned} \quad (13)$$

and note that $S_0(xL)$, $S_1(xL)$ and $S_2(xL)$ all correspond to RG-accessible functions, based upon the information given in (1). Indeed, the program of optimal RG-improvement is nothing more than the explicit closed-form evaluation of these functions, and their subsequent incorporation into the calculated decay rate.

To evaluate the summation $S_0(u)$, as defined by (13), we simply multiply eq. (9) by u^{p-1} and sum from $p = 1$ to infinity:

$$\begin{aligned} 0 &= \sum_{p=1}^{\infty} p T_{p,p} u^{p-1} - \beta_0 \sum_{p=1}^{\infty} (p-1) T_{p-1,p-1} u^{p-1} \\ &\quad - 5\gamma_0 \sum_{p=1}^{\infty} T_{p-1,p-1} u^{p-1} \\ &= (1 - \beta_0 u) \frac{dS_0}{du} - 5\gamma_0 S_0. \end{aligned} \quad (14)$$

We note from the definition (13) of the series $S_n(xL)$ that

$$S_n(0) = T_{n,0}. \quad (15)$$

The solution of the differential equation (14) with initial condition $S_0(0) = T_{0,0} = 1$ is

$$S_0(u) = (1 - \beta_0 u)^{-5\gamma_0/\beta_0}. \quad (16)$$

A similar procedure is employed to find S_1 , and S_2 . If we multiply eq. (10) by u^{p-2} and then sum from $p = 2$ to ∞ , we find after a little algebra that

$$(1 - \beta_0 u) \frac{dS_1}{du} - (\beta_0 + 5\gamma_0) S_1 = 5\gamma_1 S_0 - (2\gamma_0 - \beta_1 u) \frac{dS_0}{du}. \quad (17)$$

Substituting the solution (16) into the right hand side of (17) and noting that $S_1(0) = T_{1,0}$, we find that

$$\begin{aligned} S_1(u) &= \frac{5(\gamma_0\beta_1/\beta_0 - \gamma_1)/\beta_0}{(1 - \beta_0 u)^{5\gamma_0/\beta_0}} \\ &\quad + \frac{T_{1,0} - 5(\gamma_0\beta_1/\beta_0 - \gamma_1)/\beta_0 + [5\gamma_0(2\gamma_0 - \beta_1/\beta_0)/\beta_0] \log(1 - \beta_0 u)}{(1 - \beta_0 u)^{(\beta_0 + 5\gamma_0)/\beta_0}}. \end{aligned} \quad (18)$$

Similarly, we can multiply eq. (11) by u^{p-3} and then sum from $p = 3$ to ∞ to obtain the differential equation

$$\begin{aligned} (1 - \beta_0 u) \frac{dS_2}{du} &- (2\beta_0 + 5\gamma_0) S_2 \\ &= (\beta_1 u - 2\gamma_0) \frac{dS_1}{du} + (\beta_1 + 5\gamma_1) S_1 + (\beta_2 u - 2\gamma_1) \frac{dS_0}{du} + 5\gamma_2 S_0 \end{aligned} \quad (19)$$

whose solution is given by eq. (2.28) of ref. [2].

2 Order-by-Order Elimination of Renormalization Scale Dependence

If one substitutes solutions for $S_0(xL)$, $S_1(xL)$ and $S_2(xL)$ into eq. (13), one obtains the following optimally RG-improved version of the series S [2]:

$$\begin{aligned}
S &\cong S_0(xL) + xS_1(xL) + x^2S_2(xL) \\
&= w^{-60/23} + x \left[-\frac{18655}{3174}w + 10.1310 + \frac{1020}{529} \log w \right] w^{-83/23} \\
&+ x^2 \left[13.2231w^2 - \left(47.4897 + \frac{3171350}{279841} \log w \right) w \right. \\
&+ \left. \left(61.0515 + 25.5973 \log w + \frac{719610}{279841} \log^2 w \right) \right] w^{-106/23}
\end{aligned} \tag{20}$$

with

$$w \equiv 1 - \beta_0 xL \tag{21}$$

and with x and L given by eq. (6).

When multiplied by $m_b^5(\mu)$, this expression has the remarkable property of being almost entirely independent of μ . Figure 1 of ref. [2] displays a head to head comparison of the μ dependence of eq. (20), and the same expression with S given by the known terms of eq. (1). For the latter case, $[m_b(\mu)]^5 S$ is seen to decrease from $\approx 2500 \text{ GeV}^5$ to $\approx 1500 \text{ GeV}^5$ as μ decreases from 1.5 GeV to 9.0 GeV. For eq. (20), however, the quantity $[m_p(\mu)]^5 S$ is seen to be $1816 \pm 6 \text{ GeV}^5$ over the same range of μ , effectively removing all μ -dependence from the optimally RG-improved two-loop calculation.

Such elimination of renormalization-scale dependence via optimal RG-improvement is also upheld for a number of perturbative expressions, including QCD corrections to the inclusive semileptonic decay of B-mesons to charmed states ($B \rightarrow X_c \ell^- \bar{\nu}_\ell$), QCD corrections to Higgs boson decays, the perturbative portion of the QCD static potential function, the (Standard-Model) Higgs-mediated $WW \rightarrow ZZ$ cross section at very high energies, and QCD sum-rule scalar- and vector-current correlation functions [2]. This last example is of particular relevance for QCD corrections to the benchmark electromagnetic cross-section ratio $R(s) = \sigma(e^+e^- \rightarrow \text{hadrons})/\sigma(e^+e^- \rightarrow \mu^+\mu^-)$. Such QCD corrections are proportional to the imaginary part of the vector-current correlation function series, a series which is fully known to three subleading orders in α_s [6]. For five active flavours, we have

$$\begin{aligned}
S &\equiv 3R(s)/11 \\
&= 1 + x + \left(1.40924 + \frac{23}{12}L \right) x^2 + \left(-12.8046 + 7.81875L + \frac{529}{144}L^2 \right) x^3 + \dots
\end{aligned} \tag{22}$$

where $x = \alpha_s(\mu)/\pi$, as before, and where L is now the logarithm

$$L \equiv \log(\mu^2/s). \tag{23}$$

Note that dependence on the physical scale s resides entirely in the logarithm, and that the all-orders series (22) for S , a measurable quantity, is necessarily impervious to changes in μ . However, progressive truncations of (22) introduce progressively larger amounts of renormalization scale dependence. For example, if the series S is truncated after all its known terms, as listed in eq. (22), we find for $\sqrt{s} = 15$ GeV that to order x^3 , S increases modestly from 1.0525 to 1.0540 as μ increases from 7.5 to 30 GeV.¹ Had we truncated the series (22) following its $\mathcal{O}(x^2)$ term, we find that such a truncation of S now decreases from 1.056 to 1.053 over the same range of μ , doubling the magnitude of μ -dependence evident over this range. Finally, if we consider only the lowest order correction to unity ($S = 1 + x(\mu)$), we find that S decreases from 1.061 to 1.045 as μ increases from 7.5 GeV to 30 GeV.

Optimal RG-improvement of the known terms of the series (22) has been shown by the same methods delineated above to lead to the following expression [2]:

$$S = 1 + x/w + x^2 [1.49024 - 1.26087 \log w] / w^2 + x^3 [0.115003w - 12.9196 - 5.14353 \log w + 1.58979 \log^2 w] / w^3 + \dots \quad (24)$$

where w is given by the definition (21), but with L now given by eq. (23). Eq. (24) is, of course, really a restructured version of the same infinite series as eq. (21), and similarly must be independent of μ when taken to all orders. However, for the series (24) such imperviousness to changes in renormalization scale is now evident on an order-by-order basis. Truncation of the series (24) after its first nonleading term (i.e., $S = 1 + x/w$) still provides an expression that exhibits less variation with μ than all four known terms of the series (22). As μ increases from 7.5 to 30 GeV, we find for $\sqrt{s} = 15$ GeV that $1 + x/w$ decreases from 1.0524 to 1.0516. Similarly, truncation of the series (24) after its third term leads to a slow decrease from 1.0557 to 1.0553, and retention of all four known terms leads to an almost flat value (1.05372 ± 0.00004) over the same 7.5 GeV - 30 GeV spread in μ .

Consequently, we see that the program of optimal RG-improvement, as described above, is seen to yield *order-by-order* perturbation-theory predictions which are almost entirely decoupled from the particular choice of renormalization scale.

3 Lowering the Infrared Bound on Perturbative Approximations to $R(s)$

The optimally RG-improved series (24) is term-by-term singular when $w = [1 - \beta_0 x(\mu) \log(\mu^2/s)]$ is zero. Since s is the external momentum scale characterising the physical e^+e^- annihilation process, we see that the use of (24) is possible only if [3]

$$s > \mu^2 \exp \left(-\frac{\pi}{\beta_0 \alpha_s(\mu)} \right). \quad (25)$$

¹In all estimates presented here, $\alpha_s(\mu)$ is assumed to evolve via its known 4-loop order β -function from $\alpha_s(M_z) = 0.118$ [7].

It is particularly curious that this bound on s corresponds to the infrared bound on the naive one-loop ($1L$) running couplant ($x_{1L} = (\alpha_s(\mu))_{1L}/\pi$)

$$\mu^2 \frac{dx_{1L}}{d\mu^2} = -\beta_0 x_{1L}^2 \quad (26)$$

whose solution

$$\alpha_s(\mu) = \frac{\pi}{\beta_0 \log(\mu^2/\Lambda_{1L}^2)} \quad (27)$$

can be inverted as follows to express the $1L$ infrared cut-off in terms of some reference value of $\alpha_s(\mu)$:

$$\Lambda_{1L}^2 = \mu^2 \exp\left(-\frac{\pi}{\beta_0 \alpha_s(\mu)}\right). \quad (28)$$

Consequently, for a given choice of μ for which $\alpha_s(\mu)$ is known (e.g. the value $\alpha_s(m_\tau)$ extracted from τ -decay experiments), we see that each of the terms in the optimally RG-improved series (24) diverges as s approaches Λ_{1L}^2 from above.

The idea that QCD perturbative series break down in the infrared is hardly new, but the location of this breakdown is usually identified with an IR-divergence in the *all-available-orders* evolution of $\alpha_s(\mu)$, not the naive $1L$ Landau pole of eq. (28). To consider the IR boundary of QCD corrections to e^+e^- annihilation, we find for three active flavours that QCD corrections to the e^+e^- annihilation cross-section are, as before, obtained from the perturbative series within the imaginary part of the QCD vector current correlation function [6]:

$$\begin{aligned} R(s)/2 &= 1 + x + \left(1.63982 + \frac{9}{4}L\right)x^2 \\ &+ \left(-10.2839 + 11.3792L + \frac{81}{16}L^2\right)x^3 \\ &+ \dots \end{aligned} \quad (29)$$

where $x = \alpha_s(\mu)$ and where $L = \log(\mu^2/s)$. The standard phenomenological approach to this series is to first recognize its all-orders invariance under changes in μ , and then to assume such invariance applies to truncation of the series after its four known terms. This (seldom stated) assumption [8] motivates the choice $\mu^2 = s$ (i.e. $L = 0$) leading to the usual $n_f = 3$ expression [7],

$$R(s) = 2 \left[1 + x(\sqrt{s}) + 1.63982 x^2(\sqrt{s}) - 10.2839 x^3(\sqrt{s}) + \dots \right]. \quad (30)$$

Such an expansion necessarily falls apart in the infrared when $x(\sqrt{s})$ becomes large. Indeed, the large coefficient of $x^3(\sqrt{s})$ in (30) manifests itself in a sharp drop in $R(s)$ at $\sqrt{s} \cong 650$ MeV [3].

It is interesting to compare the known terms in eq. (30) to the optimally RG-improved version of the known terms in eq. (29) [2, 3]:

$$R(s) = s [1 + x(\mu)/w(\mu, s)]$$

$$\begin{aligned}
& + x^2(\mu) \left(1.63982 - \frac{16}{9} \log(w(\mu, s)) \right) / w^2(\mu, s) \\
& + x^3(\mu) (-1.31057 w(\mu, s) - 8.97333 \\
& - 8.99096 \log(w(\mu, s)) + 3.16049 \log^2(w(\mu, s))) / w^3(\mu, s) \Big] \quad (31)
\end{aligned}$$

where

$$w(\mu, s) = 1 - \frac{9}{4} x(\mu) \log(\mu^2/s). \quad (32)$$

We first note that $x(\mu)$ and $x(\sqrt{s})$ occurring in eqs. (29), (30), (31) and (32) are evolved through all known orders of the β -function (8). Consequently, we are free to assign to eq. (31) an $n_f = 3$ empirical value for μ ($\mu = m_\tau$ or, alternatively, $\mu = 1$ GeV) safely outside the infrared region. To facilitate comparison of eqs. (30) and (31), we will assume that $x(\sqrt{s})$ devolves via the full β -function from this same initial choice of μ until, for a sufficiently small value of s , $x(\sqrt{s})$ becomes infinite. The point here is that for $n_f = 3$, the first four known terms of the β -function are all same-sign: $(\beta_0 x^2 + \beta_1 x^3 + \beta_2 x^4 + \beta_3 x^5) > \beta_0 x^2$. Thus for a given value of x , the full β -function is more negative than the one-loop β -function of eq. (26). Since the evolution of both equations is referenced to the same initial value μ , the all-orders couplant $x(\sqrt{s})$ will diverge at a value of s that is *larger* than Λ_{1L}^2 , the Landau pole of eq. (26). Hence the series (31) will probe more deeply into the infrared than the series (30) for $R(s)$.

As an example, consider the running couplant $x(\sqrt{s})$ obtained via a two-loop β -function $\beta(x) = -\beta_0 x^2 - \beta_1 x^3$. Solution of the differential equation $s dx/ds = \beta(x)$ with the initial value $x(\mu)$ yields the exact constraint

$$\beta_0 \log \left(\frac{\mu^2}{s} \right) = \frac{1}{x(\mu)} - \frac{1}{x(\sqrt{s})} + \frac{\beta_1}{\beta_0} \log \left[\frac{x(\mu)[x(\sqrt{s}) + \beta_0/\beta_1]}{x(\sqrt{s})[x(\mu) + \beta_0/\beta_1]} \right]. \quad (33)$$

The two-loop Landau pole s_{2L} occurs when $x(\sqrt{s_{2L}}) \rightarrow \infty$, i.e., when

$$\begin{aligned}
s_{2L} &= \mu^2 \exp \left(-\frac{1}{\beta_0 x(\mu)} \right) \left[1 + \frac{\beta_0}{\beta_1 x(\mu)} \right]^{\beta_1/\beta_0^2} \\
&= \Lambda_{1L}^2 \left[1 + \frac{\beta_0}{\beta_1 x(\mu)} \right]^{\beta_1/\beta_0^2}. \quad (34)
\end{aligned}$$

Since β_0 , β_1 and $x(\mu)$ are all positive, $s_{2L} > \Lambda_{1L}^2$. Note that β_2 and β_3 [9] persist in being positive. Consequently, for a given initial value $x(\mu)$, the singularity in eq. (31) that occurs at $w(\mu, s) = 0$ (i.e., at $s = \Lambda_{1L}^2$), continues to precede the Landau singularity of $x(\sqrt{s})$ characterizing eq. (30). Thus, the optimally RG-improved eq. (31) extends the applicability of perturbative QCD to lower values of s than in the conventional eq. (30) approach to $R(s)$, as is explicitly shown in Fig. 2 of ref. [3].

Finally, we note that one must distinguish between the infrared limitations on the domain of perturbative approximations to $R(s)$, and any such limitations on $R(s)$ itself. For example, each term within the toy series $\sum_{n=0}^{\infty} [-x/(s - \Lambda^2)]^n$ diverges at $s = \Lambda^2$, but the function $(s - \Lambda^2)/(s - \Lambda^2 + x)$ from which this series is extracted, is clearly finite

at $s = \Lambda^2$. Similarly, the all-orders function $R(s)$, as opposed to truncations of its series representations, may indeed proceed smoothly to a finite limit as $s \rightarrow 0$ [10]. If such is the case, the best one can hope for in a perturbative series representation of $R(s)$ is the deepest possible penetration of that series into the low- s region.
